## Abstract

This study explored the effects of retrieval and feedback on test-potentiated new learning. Participants read a text divided into three parts, between which they engaged in either episodic retrieval, semantic retrieval, or rereading. Participants in the retrieval conditions were randomly assigned to either receive or not to receive feedback on their achievement. We administered multiple choice questions whose distractors were designed specifically to facilitate proactive interference. Planned analyses showed that participants in the episodic retrieval condition scored higher on the final test than participants in the other two groups. Feedback was found to have no bearing on new learning — neither on its own, nor via interaction with the interpolated activity type. No effect regarding the number of proactive intrusions was found, although exploratory Bayesian analyses preclude rejecting an effect. Results are interpreted in terms of metacognitive theories that have previously been suggested as an explanation of the effect.

Keywords: test-potentiated new learning, interpolated activity, feedback, semantic retrieval, episodic retrieval

## General Audience Summary

Contemporary cognitive science has shown that activities people engage in after a study session have a significant effect on the learning outcome. The choice of whether to simply reread, or to rather attempt to recall the studied information from memory, has a non-negligible impact on long-term retention, with studies overwhelmingly supporting the latter option. Furthermore, trying but failing to retrieve a piece of information may have a silver lining in that it can actually make it more susceptible to successful memory processing in the future. It is assumed that active retrieval engages and refines generic mental processes that are also called upon at a more critical hour — during some final examination.

A closely related line of research seems to suggest that a memory test can even boost future learning of unrelated information. This somewhat puzzling effect is called test-potentiated *new* learning. Moreover, a number of studies examined a possibility that the key ingredient is not necessarily a test pertaining to the studied information. It was suggested that retrieval in general, be it from short-term or long-term memory, could be the cause of improvement in future learning. In short, retrieval itself seems to enhance memory for events that follow.

However, these studies mostly used fairly simple learning materials such as word lists. Our study, therefore, examined whether this effect generalises to everyday circumstances. Three groups of participants studied three paragraphs of text in sequence, and engaged in different activities between studying. One group reread the texts, another was given general knowledge questions, and the last group was given questions concerning the paragraphs. Our results show that when it comes to learning information that is typically found in an educational context, the safest bet would be to insert memory tests related to the studied material in between your study sessions.

## The role of retrieval type and feedback in test-potentiated new learning

The term “testing effect” refers to the finding that, when it comes to long-term retention of a piece of information, retrieving it from memory trumps restudying it (Adesope, Trevisan, & Sundararajan, 2017; Glover, 1989; Karpicke & Roediger, 2008; Roediger III & Butler, 2011; Roediger III & Karpicke, 2006a, 2006b; Rowland, 2014). Besides directly enhancing retention through repetition of *successful* retrieval, testing effects can be brought about indirectly (Arnold & McDermott, 2013b; Roediger III & Karpicke, 2006a; but for a different view, see Kornell, Klein, & Rawson, 2015). For example, *unsuccessful* retrieval attempts can, through subsequent repeated encoding, generate test-potentiated (re)learning (TPL), whereby taking more tests increases the proportion of *newly* retrieved items in a test immediately following a restudy episode (Arnold & McDermott, 2013a, 2013b; Izawa, 1966, 1970; Kornell, Hays, & Bjork, 2009; Wissman & Rawson, 2018).

More importantly, following an initial impetus provided by Szpunar, McDermott, and Roediger (2008), who built upon earlier findings (Darley & Murdock, 1971; Tulving & Watkins, 1974), a decade of research has shown that retrieving previously studied information can even facilitate the acquisition of *new* information (Chan, Meissner, & Davis, 2018; Pastötter & Bäuml, 2014; Yang, Potts, & Shanks, 2018). If, within a multi-list learning paradigm, each subsequent study episode contains new items, testing the memory for those items after each learning episode still yields a greater number of correct responses and a decrease in proactive interference (PI) on a test pertaining to the final learning episode (e.g. Szpunar, Khan, & Schacter, 2013; Szpunar et al., 2008; Wissman, Rawson, & Pyc, 2011). Following the reasoning of Chan, Meissner, and Davis (2018), we use the term “test-potentiated *new* learning” (TPNL) to denote this effect. Having been investigated mainly using simple materials, a particularly important question for real-world applications is whether TPNL generalises to materials more complex than single words and word pairs. The research conducted in the preceding decade mostly points to a positive answer.

Wissman et al. (2011) were the first to ask whether the scope of TPNL extends to prose passages, and they did find a consistent effect using a free recall measure throughout their five experiments. As for its possible cause, evidence for an improvement via integration of

related information or via PI reduction — an explanation which figures prominently in the multi-list paradigm literature (Darley & Murdock, 1971; Szpunar et al., 2008) — was rather unconvincing. The effect was observed regardless of the interrelatedness of passages, and, possibly owing to the usage of text passages and free recall, overall intrusion rates were quite low. The authors subscribe to a view that retrieval attempts may promote the use of more effective encoding strategies.

In a similar study using text passages, Divis and Benjamin (2014) hypothesised that retrieval attempts enhance internal context fluctuations, which may lead to TPNL. If this scenario were true, then perhaps *any* interpolated task causing a context change might also produce TPNL. Context changes have mostly been studied in terms of their role in *directed forgetting*, where it has been proposed that they could reduce interference (e.g. Sahakyan & Kelley, 2002). Since people store contextual alongside the target information during learning (Howard & Kahana, 2002; Mensink & Raaijmakers, 1988; Tulving & Thomson, 1973), the interplay between the two may affect memory performance. Regarding TPNL, it has been proposed that testing causes an internal context change relative to the one during study (Jang & Huber, 2008; Jonker, Seli, & MacLeod, 2013; Pastötter, Schicker, Niedernhuber, & Bäuml, 2011). Hence, items from successive study episodes might be updated with unique contextual information related to retrieval (Karpicke, Lehman, & Aue, 2014; Lehman, Smith, & Karpicke, 2014), while those encountered last remain associated only with the study context.

For example, while knowing that each study episode contains new items, being aware that a recalled item was actually retrieved on a prior test could prevent subjects from providing erroneous responses, which may underlie the PI reduction observed in TPNL (Johnson, Hashtroudi, & Lindsay, 1993; Szpunar et al., 2008). Put differently, additional contextual cues increase the disparity between pre- and post-retrieval items, providing an advantage to the latter by constraining the memory search set to items that are associated exclusively with the study context (Bäuml & Kliegl, 2013; Szpunar et al., 2008). Apart from this retrieval perspective, an encoding explanation of the effect of context changes proposes that they also induce a reset of encoding processes, making subsequent encoding more effective (Pastötter et al., 2011). This could have also been at play in the study by Wissman et al. (2011). But,

first and foremost, does any context-changing activity induce TPNL?

### **Nonepisodic recall**

One of the more curious findings in the field is that TPNL may indeed ensue not only after retrieving the previously studied material (episodic retrieval), but also after the retrieval of information unrelated to the studied material from semantic (Divis & Benjamin, 2014; Pastötter et al., 2011), or even short-term memory (Pastötter et al., 2011), although there have been unsuccessful attempts at replication (e.g. Weinstein, McDermott, Szpunar, Bäuml, & Pastötter, 2015).

Pastötter et al. (2011) let their participants learn five lists of 20 words while engaging in varied interlist activities. They either restudied the lists, recalled the words from the list, generated as many words as they could from one of four semantic categories (e.g. professions), engaged in a 2-back short-term memory task, or counted backwards from a random three-digit number. They found that only the three forms of retrieval induced TPNL. In their first experiment, Divis and Benjamin (2014) adapted the procedure from Pastötter et al. (2011). Participants learned five lists of 10 words, between which they either retrieved information from semantic memory (e.g. enumerated professions) or counted backwards by 3s from a three-digit number. Only semantic retrieval enhanced performance in final list recall. They replicated and extended these findings in their second experiment by using complex learning materials. Participants read four text passages in a self-paced manner, while engaging in one of the same two types of intervening tasks between reading.

The argument these two groups of authors invoke to explain their results is that nonepisodic retrieval tasks sufficiently alter participant's internal context, and because the last study session is not affected by an additional context shift, a beneficial segregation of the final study context from the previous ones is produced. An additional prediction stemming from the context change hypothesis is that introducing a delay between the last study episode and the final test should annul the benefits conferred by the contextual segregation because the delay offers ample opportunity for a context change even without the retrieval (Chan, Meissner, & Davis, 2018). Divis and Benjamin (2014) confirmed this in their final experiment,

but [Chan, Manley, Davis, and Szpunar \(2018\)](#) provide evidence to the contrary, and side with the strategy change explanation suggested by [Wissman et al. \(2011\)](#). [Chan, Manley, et al. \(2018\)](#), however, did not include any other supposed context-changing interpolated tasks besides episodic retrieval, which prevented assessing other predictions of the hypothesis.

Although [Divis and Benjamin \(2014\)](#) did find a reduction in PI in their first experiment, which they had predicted based on the purported isolating effect of context fluctuations, when their methodology precluded such effects in their second experiment, the results, resonating with those of [Wissman et al. \(2011\)](#), still showed TPNL. They conceded that PI reduction may not be the sole basis for the observed enhanced performance, and mention optimisation of encoding strategy as a plausible cause. Finally, it is worth noting that, apart from prose passages, positive evidence for TPNL with complex learning materials was also found using lengthy video materials ([Chan, Thomas, & Bulevich, 2009](#); [Jing, Szpunar, & Schacter, 2016](#); [Szpunar, Khan, & Schacter, 2013](#)), but in order to clarify the nature of TPNL within realistic settings, further inquiry is warranted.

## Feedback

Even though it is not necessary for the testing effect to emerge ([Roediger III & Karpicke, 2006b](#)), corrective feedback is known to augment it ([Roediger III & Butler, 2011](#)). When it is provided, corrective feedback increases learning because it promotes error correction ([Pashler, Cepeda, Wixted, & Rohrer, 2005](#)) and reassurance ([Butler, Karpicke, & Roediger, 2008](#)). Feedback is particularly important for recognition tests such as multiple-choice tests since the usual benefit testing provides might turn into a disadvantage in case the test-taker selects a lure ([Marsh, Roediger, Bjork, & Bjork, 2007](#); [Roediger III & Marsh, 2005](#)). Further, evidence points to the timing of feedback being a relevant variable when gauging its influence on learning, with delayed feedback given in bulk showing superior effects compared to immediate, piecemeal feedback ([Butler, Karpicke, & Roediger, 2007](#); [Butler & Roediger, 2008](#); [Metcalf, Kornell, & Finn, 2009](#); [Smith & Kimball, 2010](#)).

Perhaps unsurprisingly, there is a paucity of research into the potential role of feedback in TPNL because the process by which it could affect new learning is less apparent. One

possibility is that feedback may act indirectly by guiding future efforts and motivating a change in encoding strategy (Roediger III & Karpicke, 2006a). Indeed, even failed or unconfident retrieval can be conceptualised as feedback per se because it can provide insight into where additional cognitive resources should be allocated to improve performance (see e.g., Kornell et al., 2009). Moreover, providing feedback may engender additional processing (Bangert-Drowns, Kulik, Kulik, & Morgan, 1991), further enhancing context fluctuations, and perhaps increasing the likelihood of intrusions during new learning (Chan, Meissner, & Davis, 2018). Thus, the variable of corrective feedback may be a fruitful avenue for research.

## Present study

Our study had two main goals. Firstly, we sought to replicate the TPNL effect in an ecologically valid setting, by using complex learning materials and standard multiple-choice items. Secondly, there is a relative dearth of investigations using nonepisodic retrieval and recognition, and furthermore a lack of studies introducing corrective feedback (Chan, Meissner, & Davis, 2018). We therefore formed two memory tests, one of which tapped into episodic (assessing memory of the studied materials) while the other tapped into semantic memory (assessing general knowledge). Participants either were or were not given feedback upon completing an interpolated activity episode.

Even though it has been shown that, in the standard multi-list procedure, substantially larger effect sizes follow after using free recall rather than recognition-level retrieval (Chan, Meissner, & Davis, 2018), choosing to examine the impact of feedback on TPNL imposed constraints upon our choice of testing format; immediate provision of feedback would have been intractable had we chosen to use free recall. Recognition is thought to be based more on familiarity than on controlled memory search (Yonelinas, 2002), which could be the reason behind the discrepant effect sizes. We, therefore, made an effort to heed the advice provided by Chan and McDermott (2007) — constraining the time for encoding, increasing the similarity between the correct answer and the distractors, and providing subjects with ample time to respond to questions — in order to encourage the use of controlled recollection. While relevant studies did find PI to be superfluous when complex learning materials are used,

in order to explore this possibility more closely, we used multiple-choice questions designed to assess memory both in terms of correct answers and susceptibility to intrusions.

Based on the preceding discussion, if TPNL is mediated by context fluctuations, then we should find that both types of retrieval enhance new learning, whereas rereading, which is deemed unable to bring about context changes (Chan, Meissner, & Davis, 2018), does not. If PI is in fact nonessential, then we should observe the expected memory boost without necessarily seeing an accompanying decrease in PI. We assumed that presenting feedback would have a positive effect on memory performance, but only for the participants engaging in episodic recall because only they could alter their encoding strategies accordingly. Finally, we expected to find an interaction effect of activity type and feedback presentation on the number of intrusions, but did not set a specific prediction regarding its pattern.

## Methods

### Participants and design

Undergraduate and graduate phonetics and psychology students (80.8% female, median age = 21, range = [18, 31], total  $N = 207$ ) participated in the study in exchange for course credit. We employed a 2 (interpolated activity: episodic vs semantic recall)  $\times$  2 (feedback: given vs not given) between-subjects design. Rereading served as a comparison interpolated activity, which was given to an additional control group. In total, this amounts to five separate groups, to which the participants were randomly assigned.

### Materials and procedure

Participants read an expository text about weeds, drawn from a chapter in an university-level textbook. Some sentences and passages were slightly modified, so as to avoid odd language constructions; terms from the binomial nomenclature were translated, and, taking into account the characteristics of the target participant population, some plant names were removed from the text to make it more approachable. The text was divided into three interrelated parts (874, 754, and 835 words) constituting an integrated body of knowledge. Additionally,

a practice text (768 words), not directly related to any of the other three parts, was taken from the same chapter. The materials were presented on a PC, in an application constructed using the open source *oTree* framework (version 2.1.35, [Chen, Schonger, & Wickens, 2016](#)) for the *Python* programming language (version 3.6.4, October 20, 2018).

For the interpolated activity, participants either (i) answered ten multiple choice questions related to the content of the part they have previously read (episodic recall, hereafter referred to as content-related testing), (ii) answered ten general knowledge multiple choice questions (semantic recall, hereafter referred to as general-knowledge testing) or (iii) reread the same part of the text they have previously read.

Further, we manipulated whether or not participants received feedback on their accomplishment on the interpolated tests. Feedback was presented on a separate screen which listed the questions, the participant’s answers, and the correct answers in a tabular format. Incorrectly answered questions were highlighted in red, and correctly answered questions in green. After 40 seconds elapsed, a “Next” button appeared, allowing participants to proceed with reading the next part of the text. By setting this cooldown period, by emphasising that there would be a cumulative test, and by explicitly asking through written instructions, we wanted to encourage our participants to carefully examine the feedback. The feedback was presented for maximally 60 seconds, after which the application proceeded to the next part.

The general procedure is shown in [Figure 1](#). Participants were first given a brief introduction to the study, and were encouraged to carefully read and follow the written instructions. Then, they were led to a computer which was running a fullscreen instance of the *oTree* application with a randomly chosen experimental condition. There, participants read the informed consent form and, in case there were no questions, started the experiment.

After entering their personal information, participants were presented with the instructions for their first task, which was to read the practice text at a speed that comes naturally. Unbeknownst to them, the time they took to read the practice text was recorded, and used as the basis for determining the reading time limits for the remaining texts. Still, the lowest possible time limit was set to 5, and the longest to 8 minutes.

Next, participants were familiarised with the interpolated activity they were going to

Figure 1. A flowchart depicting the experimental procedure.

perform during the main part of the procedure. The content-related test group answered 4 questions based on the practice text, the general-knowledge test group answered 4 general knowledge questions, and the rereading group reread the practice text (this time with the time limit applied). Subjects in the rereading and general knowledge conditions also answered the 4 questions related to the practice text, in order to familiarise themselves with the scope and specificity level of the questions they will receive after reading the final text. All tests were self-paced and no time limit was applied. Participants assigned to the feedback condition also received feedback on their interpolated activity practice test achievement.

After the practice round, participants proceeded to the main part of the study, engaging in the interpolated activities. Depending on the condition they were assigned to, they could also receive feedback after every interpolated test. All participants were forewarned through initial instructions that there would be a cumulative test after the final part of the text, examining their knowledge of all three parts. In reality, the final test examined only the knowledge of the final part. Participants were presented with 20 novel questions examining their knowledge of that part. Through this increase of the number of questions we sought to avoid a ceiling effect on our main dependent variable, which could mask a real effect of TPNL. No feedback was presented after the final test, irrespective of the experimental condition.

In total, 44 content related questions with 4 response options were generated from the presented parts of the text. 4 questions were presented after the practice text, 10 after each of the first two parts (only to the participants in the content related test condition), and 20 after the third part of the text (to all participants). Starting from the second test, the distractor options were chosen so that (i) two distractors were plausible, but unrelated to the text, and (ii) one distractor was a term or concept mentioned in the previous part of the text — this was considered to be the “intrusive” distractor (sometimes referred to as the “intruder” in the rest of this article). For example, a question in the final test was *The agricultural habitat on which a plant grows is called the...* The response options were (a) agrobiosphere (distractor, never mentioned in the text), (b) agrosphere (intrusive distractor, mentioned in the previous part of the text), (c) biotope (distractor), (d) agrobiotope (correct answer). Further, 24 general knowledge questions were generated. These were presented

to participants in the general-knowledge test condition, after the first two parts of the text and after the practice text. The questions spanned recent history, popular culture, and art (e.g. *Kurt Vonnegut's famous anti-war novel is called...*).

The computer recorded whether a participants response was correct and whether they chose an intrusive distractor. This allowed us to compute our dependent variables — the total number of correct answers and the total number of intrusive distractors chosen.

## Results

### Exclusion criteria

Prior to analysing the data, we excluded participants based on a priori set criteria. Participants who spent less than or equal to 90 seconds on the practice text were excluded (1 exclusion). Further, we wanted to exclude participants who had no correct answers on the final test (0 exclusions). Finally, we excluded participants who had stated that they had reading deficits (3 exclusions). This left us with a total sample of 203 participants.

### Interpolated activity effect

Our first two hypotheses are concerned with the effects of different interpolated activities on the total number of correct answers and total number of intrusive distractors chosen. To test these hypotheses, we focused only on the groups which did not receive feedback ( $n = 122$ ). This was done because there was no feedback option for the rereading group, and we did not want to treat the feedback and no-feedback general-knowledge and content-related testing groups as equivalent without strong evidence supporting that assumption.

The correlation between our DVs calculated on the whole sample is  $r(201) = -.707$  (95% CI:  $[-.77, -.63]$ ,  $p < .0001$ ). Given that we have two dependent variables, which are highly correlated, we have decided to conduct a one-way MANOVA. According to [Tabachnick and Fidell \(2012\)](#), conducting a MANOVA instead of multiple ANOVAs increases the chance of discovering the effects of different treatments. Furthermore conducting a MANOVA guards against the inflation of Type 1 errors due to multiple tests of correlated dependent

Figure 2. Mean number of correct answers and mean number of intrusive distractors chosen, broken down by experimental condition. Error bars show the 95% confidence intervals around the means.

variables (Field, Miles, & Field, 2012; Tabachnick & Fidell, 2012). Finally, conducting separate ANOVAs would disregard the correlation between our two dependent variables (Field et al., 2012). Therefore, we conducted a one-way MANOVA with interpolated activity as the independent variable and the total number of correct and intrusive options chosen as dependent variables.

A power analysis conducted prior to analyzing the data (using the G\*Power software by Faul, Erdfelder, Buchner, & Lang, 2009) has shown that we should have above 80% power to detect effects which fall between small and medium (Cohen's  $f^2 \gtrsim 0.06$ ), at an  $\alpha$  level of .025, with a sample size of 110 participants. Note that larger effects are expected based on prior studies.

Pillai's V for the analysis is .126,  $p = .004$  (Wilks'  $\Lambda = .875$ ,  $p = .003$ ). The effect size, calculated as  $\omega_{mult}^2 = .109$  (bootstrap median<sup>1</sup> = .132,  $BC_{\alpha}$  95% CI = [.011, .202])<sup>2</sup>. To further inspect the relationship of the interpolated activities with our dependent variables, we

<sup>1</sup>All bootstrap estimates taken from 10000 replications.

<sup>2</sup>Cohen's  $f^2 = 0.051$  (calculated according to Equation 12 in Steyn Jr & Ellis, 2009).

conducted a Roy-Bargmann stepdown analysis, as suggested by [Tabachnick and Fidell \(2012\)](#); a linear discriminant analysis with the same aim is available in the supplementary materials). According to [Tabachnick and Fidell \(2012\)](#), the higher priority variable can be chosen based on theoretical or practical grounds. Since the total number of correct answers is the criterion that determines a student's success in a testing context, we chose this dependent variable as the higher priority one. Therefore, we first conducted an ANOVA with interpolated activity type as the independent variable and the total number of correct answers as the dependent variable.

As could be expected, the ANOVA points to a differential effect of our conditions on the total number of correct answers, with  $F(2, 119) = 7.541, p = .001$ . Following the ANOVA, we conducted an ANCOVA, with the total number of correct answers as the covariate, and the total number of intrusors as the dependent variable. The results imply a main effect of the total number of correct answers ( $F(1, 118) = 79.674, p < .0001$ ), but after we took into account the number of correct answers, we found no evidence for an effect of interpolated activity type on the total number of chosen intrusors ( $F(2, 118) = 0.844, p = .433$ ). So far, our analyses show a lack of evidence in support of our second hypothesis that the type of interpolated activity will have an effect on the number of intrusors.

In order to test our first hypothesis, we contrasted (i) the two test groups with each other, and (ii) the rereading group with the two test groups, taking only the total number of correct answers as the DV. We found a difference between the two test groups ( $t(119) = 3.62, p = .0004, g_s = 0.66, 95\% \text{ CI} = [0.21, 1.1]$ , Cohen's  $U_{3,g_s} = 74.43\%$ , probability of superiority = 67.88%). Students in the content-related-test condition score higher on the final test than students in the general-knowledge-test condition. The second contrast shows no evidence of a difference between the rereading group and the two test groups ( $t(119) = 1.355, p = .178, g_s = 0.19, 95\% \text{ CI} = [-0.19, 0.57]$ , Cohen's  $U_{3,g_s} = 57.6\%$ , probability of superiority = 55.39%). Therefore, we cannot conclude that being in the rereading condition, as opposed to being in one of the two test groups, leads to different learning outcomes. However, we believe this is due to the rereading and general-knowledge-testing groups having very similar mean numbers of correct answers ( $M = 10.88$  and  $10.47$ , respectively) These two findings are not in line

with our predictions.

### **The interaction between feedback and interpolated activity type**

The remaining hypotheses deal with the effect of feedback on the total number of correct answers and the total number of intrusors. Therefore, these analyses were carried out on the data from participants in the general and content related test conditions only ( $n = 163$ ). To test these hypotheses, we first conducted a two-way MANOVA with interpolated activity and feedback as independent variables, and total number of correct answers and total number of intrusors as the dependent variables. Again, a power analysis conducted before analysing the data has shown that we should have above 80% power to detect effects which fall between small and medium (Cohen's  $f^2 \gtrsim 0.05$ ), at an  $\alpha$  level of .025, with a sample size of 145 participants.

Pillai's V for the interpolated activity effect (calculated with type III sums of squares) is .071,  $p = .003$  (Wilks'  $\Lambda = .929$ ,  $p = .003$ ) confirming the main effect of interpolated activity type. The effect size  $\omega_{mult}^2 = .065$  (bootstrap median = .072,  $BC_\alpha$  95% CI = [.008, .140])<sup>3</sup>.

On the other hand, we found no evidence for an effect of giving feedback on the linear combination of our two dependent variables — Pillai's V = .003,  $p = .800$  (Wilks'  $\Lambda = .997$ ,  $p = .800$ ). The estimated effect size is  $\omega_{mult}^2 = 0$ .

Furthermore, we found no evidence for an interaction effect between activity type and feedback — Pillai's V = .001,  $p = .941$  (Wilks'  $\Lambda = .999$ ,  $p = .941$ ). The estimated effect size  $\omega_{mult}^2 = 0$ .

Again, we conducted a follow-up Roy-Bargmann stepdown analysis. In the ANOVA model with the total number of correct answers as the dependent variable and the type of interpolated activity, feedback and their interaction as predictors, only the type of activity seems to be relevant ( $F(1, 159) = 11.2$ ,  $p = .001$ ). This result also shows that students in the content-related-test condition score higher on the final test than students in the general-knowledge-test condition, which should be no surprise given the results of the first stepdown analysis. In the second step, we fit an ANCOVA model with the total number of

---

<sup>3</sup>Cohen's  $f^2 = 0.063$ , using Equation 12 from [Steyn Jr and Ellis \(2009\)](#).

Table 1

*ANOVA and ANCOVA models for the second Roy-Bargmann procedure.*

Term	<i>SS</i>	<i>df</i>	<i>F</i>	<i>p</i>
<b>ANOVA</b>				
Activity	109.393	1	11.200	.001
Feedback	3.904	1	0.400	.528
Activity x Feedback	0.045	1	0.005	.946
Residuals	1553.046	159		
<b>ANCOVA</b>				
Activity	0.301	1	0.175	.676
Feedback	0.173	1	0.100	.752
Total correct	63.216	1	36.760	< .0001
Activity x Feedback	0.813	1	0.473	.493
Activity x Total correct	0.862	1	0.501	.480
Feedback x Total correct	0.130	1	0.075	.784
Activity x Feedback x Total correct	1.229	1	0.715	.399
Residuals	266.551	155		

correct answers as the covariate. In this model, the type of interpolated activity ceases to be a relevant predictor ( $F(1, 155) = 0.175, p = .676$ ). Therefore, we find no evidence for an effect of the type of interpolated activity nor of feedback on the number of intrusive distractors chosen. The full models are shown in Table 1.

To summarise, contrary to our expectations, we find no evidence of an effect of feedback on the total number of correctly answered questions. Also, we found no evidence for an interaction effect of feedback and type of interpolated activity on the total number of correct answers. The same findings apply to the predictions regarding the total number of intrusors chosen.

## Discussion

The aim of this study was to explore the effects of different interpolated activities and feedback reception on learning complex materials. We found evidence for an effect of interpolated activity type on TPNL — treating the two dependent variables as manifestations of TPNL, we conducted a MANOVA, revealing that participants engaging in episodic retrieval exhibited

greater TPNL than both participants who engaged in semantic retrieval and those in the control condition. Moreover, a Roy-Bargmann stepdown analysis showed that observed differences were driven primarily by the number of correct responses, while finding no evidence for the contribution of PI.

The fact that we observed the effect of interest while employing a testing format which is known to produce the smallest effects is interesting in and of itself, and suggests that the effect should hold in conditions that are arguably the most prevalent in western educational systems. Nevertheless, our results are not entirely in line with extant research nor with the context change account of TPNL. While our results point to an exclusive role of episodic retrieval, [Pastötter et al. \(2011\)](#), for example, found that both types of retrieval can generate TPNL. Notably, these authors used simpler learning materials and free recall — both learning material complexity and testing format are known moderators of TPNL ([Chan, Meissner, & Davis, 2018](#)). However, the few studies that examined the effects of nonepisodic recall on TPNL have produced equivocal results. While two studies suggested that nonepisodic and episodic recall have comparable effects ([Divis & Benjamin, 2014](#); [Pastötter et al., 2011](#)), [Weinstein et al. \(2015\)](#) failed to show this. Among a number of methodological differences between these studies, the specific type of nonepisodic recall stands out as a possible reason behind the diverging results. While [Pastötter et al. \(2011\)](#) and [Divis and Benjamin \(2014\)](#) both used semantic generation, [Weinstein et al. \(2015\)](#) used recall from autobiographical memory. Delineating the potential distinctive effects various forms of non-episodic recall could have in the TPNL paradigm is a goal future studies may pursue.

Studies that have suggested that nonepisodic recall may serve as an effective method of learning potentiation have drawn on context theories to explain their results ([Divis & Benjamin, 2014](#); [Pastötter et al., 2011](#)). [Divis and Benjamin \(2014\)](#) proposed that retrieval processes enhance context fluctuation, thereby increasing the segregation between information acquired across study sessions. This, in turn, reduces the memory search set and PI. Having said that, they acknowledged that other encoding-based explanations such as encoding strategy optimisation or encoding resetting were not ruled out. In our study, the absence of an effect of nonepisodic retrieval on learning may be taken as evidence against a context

change account of TPNL because, presumably, retrieval from semantic memory should have produced the necessary internal context change (Pastötter et al., 2011). A Bayesian estimate of the effect of nonepisodic recall also lends support for the claim that it does not enhance learning (see supplementary materials). Notably, a basic assumption we have made is that the interpolated activity that served the function of activating retrieval from semantic memory in our study was effective.

If a context change account is inapplicable to our results, then it is unsurprising that feedback, which we proposed could enhance context fluctuations, proved completely ineffective in the nonepisodic recall condition. While we found no evidence for an effect of feedback, exploratory Bayesian analyses do not exclude the possibility of one, but the obtained estimates point to an effect which could be practically equivalent to zero. Interpreting these results warrants caution, though, since a more precise estimate of the effect is desirable. Assuming the effect of feedback was in fact insignificant, this may have occurred because content-related questions in and of themselves gave participants the information they required in order to adjust their encoding strategy, thereby rendering redundant the otherwise positive influence of explicit feedback (Kornell et al., 2009; Roediger III & Karpicke, 2006a).

Recently, Chan, Meissner, and Davis (2018) provided a meta-analysis and comprehensive overview of the literature, identifying several viable explanations for TPNL. Besides context theories, whose main points are outlined above, *resource theories* generally posit that testing increases cognitive resources either by (i) reducing encoding-based PI (e.g. Nunes & Weinstein, 2012; Szpunar et al., 2008; Wahlheim, 2015; Weinstein, McDermott, & Szpunar, 2011), (ii) restoring encoding/attentional resources (e.g. Pastötter et al., 2011), or by (iii) altering mind wandering patterns to focus them more on the learning material (e.g. Jing et al., 2016; Szpunar, Khan, & Schacter, 2013; Szpunar, Moulton, & Schacter, 2013). A circumscription of separate learning episodes is at the core of both resource and context accounts, but its effect on learning is different depending on the outlook. According to the former, isolating a learning episode through attempts at recall increases resources for subsequent learning by preventing *encoding-based* PI. On the other hand, context theories emphasise later *retrieval* processes, whereby isolating an earlier learning episode reduces the memory search set for

retrieval. From our data we gather that even a hybrid account, where internal context shifts increase resources by resetting encoding processes (Pastötter et al., 2011), is not a suitable explanation.

While resource theories revolve around the amount of deployable cognitive resources, *metacognitive theories* emphasise the optimisation of their deployment, regardless of their amount. Thus, using metacognitive knowledge gained through retrieval attempts (e.g. Chan, Manley, et al., 2018; Cho, Neely, Crocco, & Vitrano, 2017), and perhaps even failures of retrieval (Bahrick & Hall, 2005), learners can adjust their strategies. We believe this to be the most fitting explanation for our data (Chan, Manley, et al., 2018; Wissman et al., 2011). In our study, only those participants who gained familiarity with the questions and type of knowledge the final test would assess were thus given the opportunity to evaluate their encoding strategies and to modify them accordingly. Ultimately, only they demonstrated an increase in the number of correct answers on the final critical test.

In line with these proposals, recent studies have shown that retrieval modifies the learner’s approach to new information (Cho et al., 2017; Soderstrom & Bjork, 2014), which may even lead to superior semantic organisation of acquired knowledge (Chan, Manley, et al., 2018; Jing et al., 2016), which is also of central importance for *integration theories* of TPNL (Chan, Meissner, & Davis, 2018). For example, in a recent investigation using multi-list learning, Chan, Manley, et al. (2018) found that, compared to untested groups, the group subjected to interpolated testing displayed an increase in category-based clustering during free recall. They ascribe this to an adoption of more efficient encoding/retrieval strategies, which may activate other relevant learning processes such as relational processing. A similar pattern is often observed in studies exploring the testing effect, where a greater number of tests is associated with improved organisation of output displayed upon testing (Karpicke, 2012; Zaromb & Roediger, 2010). Importantly, the accounts mentioned above are not mutually exclusive. One can easily imagine how a strategy shift could reduce PI and foster integration.

Finally, we have to address certain methodological concerns. In our study, participants were thoroughly informed regarding the activities they would encounter during the procedure, including the final test following the last reading episode. The typical instruction given

to participants in the TPNL paradigm is that interpolated activities will be determined randomly (Yang et al., 2018). Thus, an attempt is made to equalise expectations of a final test across conditions, and to ensure continued processing of materials across the study sequences. Nevertheless, learners dynamically adjust their expectations based on their experiences of the procedure, regardless of the instructions they are given (Weinstein, Gilmore, Szpunar, & McDermott, 2014). If they take a test, they will more likely expect another one, and such expectations are known to influence encoding (e.g. Szpunar, McDermott, & Roediger, 2007).

It is worth mentioning that our choice of learning materials could have prevented us from finding evidence in favour of context theories and an account based on the reduction of PI. However, previous work has shown that release from PI may play basically no role when it comes to learning complex materials (Divis & Benjamin, 2014; Wissman et al., 2011). The recognition-level method which we employed showed no signs of PI beyond those expected to occur by chance alone. Admittedly, limiting the number of choices by displaying possible answers may have diluted the interference effect other unwritten pieces of information might have had, if we had used free recall instead.

Further, we cannot exclude the possibility that our interpolated activities had differential effects on our participants' motivation. Several participants remarked that the text was tedious, and it is possible that the motivation of participants in the episodic retrieval condition persisted throughout the procedure, while that of the other participants waned as the procedure progressed. However, if this were true, we should have observed the lowest scores in the rereading group. Yet, this is not the case. Furthermore, we find no reason to believe that answering general knowledge questions is less interesting than answering questions about weeds, and presume that the former would, therefore, help sustain motivation. On the other hand, differences in engagement could have been caused by unequal task difficulties — the mean proportions of correctly answered questions are larger in the content-related than in the general-knowledge testing conditions. Importantly, the mean proportion of correct answers on the first interpolated content-related test is higher than on the second. If the tests were equally difficult, and if there had been a TPNL effect, we would expect higher scores on the second test. This points to the tentative conclusion that the interpolated tests themselves

differed in difficulty. Thus, we cannot reject the possibility that differing difficulties affected our participants' achievement. However, difficulty of the interpolated tasks does not appear to be of consequence in this matter (Divis & Benjamin, 2014; Pastötter et al., 2011; Sahakyan & Hendricks, 2012).

To conclude, our findings confirm the effect of episodic recall on TPNL, but we fail to find evidence for an effect of semantic recall. Further, evidence for an effect of feedback is also lacking. Our data are generally aligned with predictions stemming from metacognitive theories of TPNL, and speak against PI reduction accounts within the wider framework of resource theories.

### Author Contributions

All three authors participated in the experimental design and design of the materials. MP programmed the application used for data collection. MP and DV collected the data and analysed it. MP and DV wrote the manuscript, DI served as editor.

### Acknowledgements

We would like to thank every one of our participants for making this study possible. Also, we would like to thank Marijana Glavica, our librarian, who has been tremendously helpful around data archiving and preparations for preprint publication.

### Notes

Analyses conducted using the *R* language (R Core Team, 2019). Bootstrap conducted using the *boot* package (Canty & Ripley, 2017). Methods and analyses written using *rmarkdown* (Allaire et al., 2019) and *knitr* (Xie, 2019). The package *car* (Fox & Weisberg, 2011) was used to obtain type III sums of squares. *compute.es* (Re, 2013) was used to obtain effect sizes for contrasts. *kableExtra* was used to help generate tables (Zhu, 2019). Other utilities used are *tidyverse* (Wickham, 2017), *magrittr* (Bache & Wickham, 2014), *here* (Müller, 2017),

*conflicted* (Wickham, 2018), *psych* (Revelle, 2018).

### Funding Information

This study was conducted under the project *E-rudito: An advanced online educational system for smart specialization and jobs of the future* (KK.01.2.1.01.0009.), which is funded from the European Regional Development Fund, Operational programme competitiveness and cohesion 2014–2020.

### Open Practices Statement

The analysis plan was preregistered on GitHub (`analysis-plan.md`; first commit of analysis plan: `b101f42`; final relevant commit: `16afea3`), as were the hypotheses (`design.md`; first commit of hypotheses: `b101f42`; final commit: `dd0f863`). The repository also serves all project materials, data and analyses scripts, together with the whole project history. It can be found at <https://github.com/ffzg-erudito/inter-testing-feedback-2018>. Materials are also available through <https://osf.io/gk9a3/>. The data is also hosted on <https://dataverse.ffzg.unizg.hr/dataset.xhtml?persistentId=doi:10.23669/JVNVNR>.

There were certain deviations from the original analysis plan. Initially, we had planned to do a robustness check of our findings using data with an additional exclusion criterion, based on the number of times each participant had read each of the three parts of the main text. This analysis was never conducted because (i) applying this criterion would have lead to unacceptably low power and (ii) the participants' estimates of the number of times they had read each part were similarly distributed across all conditions. Further, we had planned to conduct a TOST procedure to test whether there is no difference between the content-related and general-knowledge testing groups. This analysis was not conducted because we did find a difference. A Bayesian t-test was also considered for the same comparison, but was dropped early on due to some conceptual concerns.

Also, our original second hypothesis suggested a differential effect of activity type on PI rates. Specifically, we expected that participants engaging in episodic retrieval would display

the lowest susceptibility to PI, followed by participants in the semantic retrieval condition, and finally by those tasked with rereading. Upon further examination of the literature, our expectations changed, but this had no bearing on the analyses, which remained the same nevertheless.
